

Can You Translate that into Man?

Commercial Machine Translation Systems Include Stylistic Biases

Abstract

The main goal of machine translation has been to convey the correct content. Stylistic considerations have been at best secondary. We show that as a consequence, the output of three commercial machine translation systems (Bing, DeepL, Google) make demographically diverse samples from five languages “sound” older and more male than the original. Our findings suggest that translation models reflect demographic bias in the training data. This opens up interesting new research avenues in machine translation to take stylistic considerations into account.

1 Introduction

Translating *what* is being said is arguably the most important aspect of machine translation, and has been the main focus of all its efforts so far. However, *how* something is said also has an impact on how the final translation is perceived. Mirkin et al. (2015) have pointed out that demographic aspects of language do play a role in translation, and could help in personalization. In many cases, capturing the style of a document is equally important as its content: translating a lover’s greeting as “I am entirely pleased to see you” might be semantically correct, but seems out of place. Demographic factors (age, gender, etc.) all manifest in language, and therefore influence style: we do not expect a 6-year old to sound like an adult, and would not translate a person to sound differently gendered. However, in this paper we show that that is essentially what happens in machine translation: authors sound on average older and more male.

Prior work (Rabinovich et al., 2017) has shown that the signal for gender prediction is weakened in translations. We substantially extend this analysis in terms of languages, demographic factors, and types of models, controlling for demographically representative samples. We show the direction in

which the predicted demographic factors differ in the translations, and find that there are consistent biases towards older and more male profiles.

In this paper, we use demographically representative author samples from five languages, translate them with three commercially available machine translation systems (Google, Bing, and DeepL), and compare the true demographics with the predicted demographics of the translations (as well as a control predictor trained on the same language). Without making any judgment on the translation of the content, we find that there are large discrepancies in the perceived demographics, and that translation tends to make the writers slightly older and considerably more male than they were.

Contributions We empirically show how translations affect the demographic profile of a text. We release our data set at <https://github.com/MilaNLPProc>.

2 Data

We use the Trustpilot data set from Hovy et al. (2015), which provides reviews in different languages, and includes information about age and gender. We use only English, German, Italian, French, and Dutch reviews, based on two criteria: 1) availability of the language in translation models, and 2) sufficient data for representative samples (see below) in the corpus. For the English data, we use US reviews, rather than UK reviews, based on a general prevalence of this variety in translation engines.

2.1 Translation Data

For each language, we restrict ourselves to reviews written in the respective language (according to `langid`¹ (Lui and Baldwin, 2012)) that have both age and gender information. We use

¹<https://github.com/saffsd/langid.py>

the CIA factbook² data on age pyramids to sample 200 each male and female. We use the age groups given on the factbook, i.e., 15–24, 25–54, 55–64, and 65+. Based on data sparsity in the Trustpilot data, we do not include the under-15 age group. This results in five test sets of about 400 instances each (the exact numbers vary slightly according to rounding and the proportions in the CIA factbook data), balanced for binary gender. The exception is Italian, where the original data is so heavily skewed towards male reviews that even with downsampling we only achieve a 48:52 gender ratio.

We then translate all non-English test sets into English, and the English test set into all other languages, using three commercially available machine translation tools: Bing, DeepL, and Google Translate.

2.2 Profile Prediction Data

All instances not selected as test set are used to select training data for the respective age and gender classifiers (see next section). Since we want to fairly compare across languages, the training data sets need to be of comparable size. We are therefore bounded by the size of the smallest available subset (Italian). We sample about 2500 instances per gender, according to the respective age distributions. This results in about 5000 instances per language (again, the exact number varies slightly based on the availability of samples for each group and rounding). We again subsample to approximate the true age and gender distribution, since, according to Hovy et al. (2015), the data skews strongly male, while otherwise closely matching the official age distributions.

3 Methods

In order to assess the demographic profile of a text, we train separate age and gender classifiers for each language. This allows us to compare the predicted profiles in the original language with that of the translation, and both to the known true demographics of the test data.

We use a simple Logistic Regression models with L_2 regularization over 2-6 character-grams.³ The numbers in Table 1 indicate that both age and gender can be inferred reasonably well across all

of the languages. We use these classifiers in the following analyses.

	de	en	fr	it	nl
gender	0.65	0.62	0.64	0.62	0.66
age	0.52	0.53	0.45	0.52	0.49

Table 1: Macro-F1 for age and gender classifiers on each language.

For each non-English sample, we predict the age and gender of the author in both the original language (using the language’s respective classifier from above, i.e., a classifier trained on German to predict German test data) and in each of the three English translations (using the respective English from above, i.e., using the classifier trained on English to predict the Google, Bing, and DeepL translations of the German test set).

For the English data, we first translate it into each of the other languages with each of the three translation systems (i.e., create a German, French, Italian, and Dutch translation from each Google, Bing, and DeepL), and again predict the author demographics in the original English test set (using the classifier trained on English), and in each of the translated versions (using the classifier trained on the respective language).

We can then compare the distribution of age groups and genders in the predictions with the true, sampled distributions. If there is *classifier bias*, both the predictions based on the original language and the predictions based on the translations should be skewed in the same direction. We can measure this difference by computing the Kullback-Leibler (KL) divergence of the predicted distribution from the true sample distribution.

If instead there is a *translation bias*, then the translated predictions should exhibit a stronger skew than the predictions based on the original language. By using both translations from and into English, we can further tease apart the direction of this effect.

4 Results

4.1 Gender

Translating into English Table 2 shows the results when translating *into* English. It shows for each language the test gender ratio, the predicted ratio from classifiers trained in the same language, as well as their KL divergence from the ratio in

²<https://www.cia.gov/library/publications/the-world-factbook/>

³We also experimented with a convolutional neural network with attention, but did not see significantly better results, presumably due to the higher number of parameters.

the test set, and the ratio predictions and KL divergence on predictions of an English classifier on the translations from three MT systems.

For most languages, there exists a male bias in predictions of the original language. The translated English versions create an even stronger skew. The notable exception is French, which most translation engines translate in a demographically faithful manner. Dutch is slightly worse, followed by Italian (note, though, that the Italian data was so heavily imbalanced that we could not sample an even distribution for the test data). Somewhat surprisingly, the gender skew is strongest for German, swinging by as much as 15 percentage points.

Translating from English Table 3 shows the results when translating *from* English into the various languages. The format is the same as for Table 2.

Again we see large swings, normally exacerbating the balance towards men. However, translating into German with all systems produces estimates that are a lot more female than the original data. This could be the inverse effect of what we observed above. Again, there is little change for French, though we also see some female bias in two MT systems.

4.2 Age

Figure 1 shows the kernel density plots for the four age groups in each language (rows) in the same language prediction, and in the English translation. In all cases, the distributions are reasonably close, but in all cases, the predictions overestimate the largest class.

In order to delve a bit deeper into this age mismatch, we also split up the sample by decade (i.e., seven classes: 10s, 20s, etc., up to 70s+). Figure 2 shows the results. The caveat here is that the overall performance is lower, due to the higher number

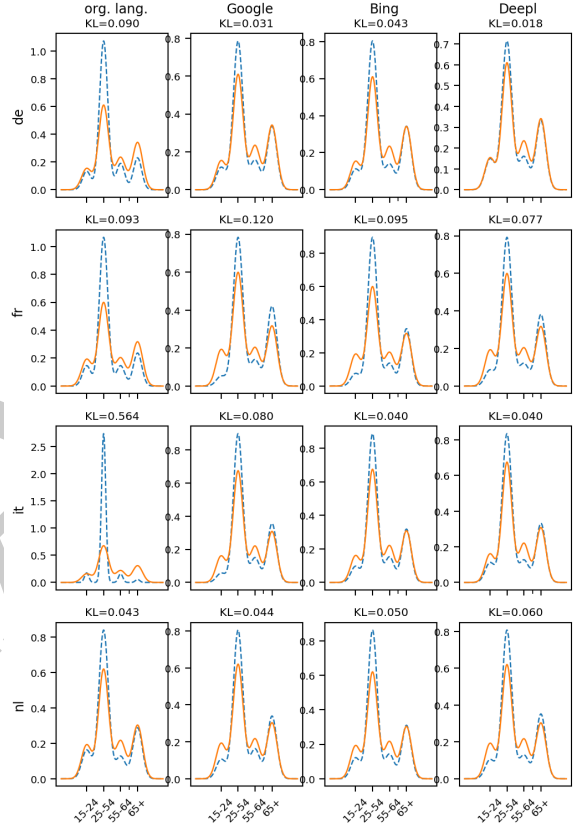

Figure 1: Density distribution and KL for age prediction in various languages and different systems in original and when translated **into** English. Solid yellow line = true distribution.

of classes. We also can not guarantee that the distribution still follows the true demographics, since we are subsampling within the larger classes given by the CIA factbook.

However, the results still strongly suggest that the observed mismatch is driven predominantly by overprediction of the 50s decade. Because this decade often contributed strongly to the largest age category (25–54), predictions did not differ as much from gold in the previous test. It also ex-

plains the situation of the Italian predictor.

In essence, English translations of all these languages, irrespective of the MT system, sound much older than they actually are.

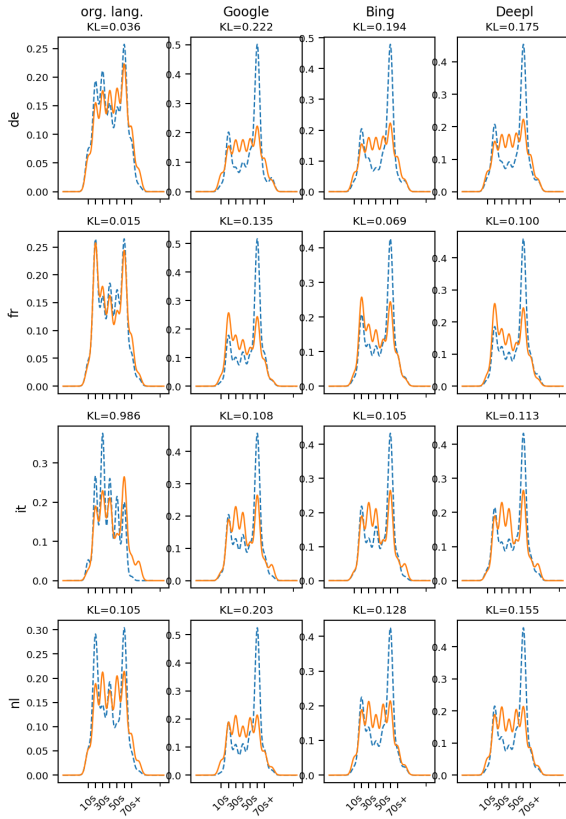

Figure 2: Density distribution and KL for decade prediction in various languages and different systems in original and when translated **into** English. Solid yellow line = true distribution.

4.3 Discrepancies between MT Systems

All three tested commercial MT systems are close together in terms of performance. However, they also seem to show the same systematic translation biases. The most likely reason is a use of biased training data. The fact that translations

into English are perceived as older and more male than translations into other languages could indicate that there is a larger collection of unevenly selected data in English than for other languages.

5 Related Work

The work by [Rabinovich et al. \(2017\)](#) is most similar to ours, in that they investigated the effect of translation on gender. However, it differs in a few key points: they show that predictive power is weakened in the translation, but do not investigate the direction of false predictions. We show that there is a definitive bias. In addition, we extend the analysis to also include age. We also use various commercially available MT tools, rather than research systems.

Recent research has suggested that machine translation systems reflect cultural and societal biases ([Stanovsky et al., 2019](#); [Escudé Font and Costa-jussà, 2019](#)), though mostly focusing on data selection and embeddings as sources.

Work by [Mirkin et al. \(2015\)](#); [Mirkin and Meunier \(2015\)](#) has set the stage for considering the impact of demographic variation ([Hovy et al., 2015](#)) and its integration in MT more general.

6 Conclusion

We test what demographic profiles author attribute tools predict for the translations from various commercially available machine translation tools. We find that independent of the MT system and the translation quality, the predicted demographics differ systematically when translating into English, on average making the author sound substantially older and more male. Translating from English into any of the other languages shows more mixed results, but similar tendencies.
